

# Scalable, Shared Memory Parallel Graph Coloring Heuristics

Assefaw Hadish Gebremedhin\*      Fredrik Manne

## Abstract

Finding a good graph coloring quickly is often a crucial phase in the development of efficient, parallel algorithms for many scientific and engineering applications. In this paper we consider the problem of solving the graph coloring problem itself in parallel. We present a simple and fast parallel graph coloring heuristic that is well suited for shared memory programming and yields an almost linear speedup on the PRAM model. We also present a second heuristic that improves on the number of colors used. The heuristics have been implemented using OpenMP. Experiments conducted on an SGI Cray Origin 2000 using very large graphs from finite element methods and eigen value computations validate the theoretical run-time analysis.

## 1 Introduction

The graph coloring problem (GCP) deals with assigning labels (called colors) to the vertices of a graph such that adjacent vertices do not get the same color. The primary objective is to minimize the number of colors used. The GCP arises in a number of scientific computing and engineering applications. Examples include, among others, time tabling and scheduling [13], frequency assignment [6], register allocation [3], printed circuit testing [8], parallel numerical computation [1], and optimization [4]. Coloring a general graph with the minimum number of colors is known to be an NP-hard problem [7], thus one often relies on heuristics to compute a solution.

---

\*Department of Informatics, University of Bergen, N-5020 Bergen, Norway {assefaw, Fredrik.Manne}@ii.uib.no

In a parallel application a graph coloring is usually performed in order to partition the work associated with the vertices into independent subtasks such that the subtasks can be performed concurrently. Depending on the amount of work associated with each vertex, there are basically two coloring strategies one can use. The first strategy emphasizes on *minimizing* the number of colors while the second strategy focuses on *speed*. As to which is more appropriate depends on the underlying problem one is trying to solve.

If the task associated with each vertex is computationally expensive then it is crucial to use as few colors as possible. There exist several time-consuming (iterative) local improvement heuristics for addressing this need. Some of these heuristics have been shown to be parallelizable [13].

If on the other hand, the task associated with each vertex is fairly small and one repeatedly has to find new graph colorings then the overall time to perform the colorings might take up a significant portion of the entire computation. See [15] for an example of this case. In such a setting it is more important to compute a usable coloring fast than spending time on reducing the number of colors. For this purpose there exist several linear time, or close to linear time, sequential greedy coloring heuristics. These heuristics have been found to be effective in coloring graphs that arise from a number of applications [4, 11]. Because of their inherent sequential nature, these heuristics are difficult to parallelize.

This paper focuses mainly on the latter strategy where our goal is to develop scalable parallel coloring heuristics based on greedy methods. Previous work on developing such algorithms has been performed on distributed memory computers using explicit message-passing. The speedup obtained from these efforts has been discouraging [1]. The main justification for using these algorithms has been access to more memory and thus the ability to solve problems with very large graphs. It is to be noted that the current availability of shared memory computers where the entire memory can be

accessed by any processor makes this argument less significant now.

The development of shared memory computers has been accompanied by the emergence of new shared memory programming paradigms of which OpenMP has become one of the most successful and widely used [16]. OpenMP is a directive-based, fork-join model for shared memory parallelism.

In this paper we present a fast and scalable parallel graph coloring algorithm suitable for the shared memory programming model. In our context, scalability of a parallel algorithm is a measure of its capacity to increase speedup as the number of processors is increased for a given problem size. Our algorithm is based on first performing a parallel pseudo-coloring of the graph. This coloring might contain adjacent vertices that are colored with the same color. To remedy this we perform a second parallel step where any inconsistencies in the coloring are detected. These are then resolved in a final sequential step. An analysis on the PRAM model using  $p$  processors for a graph with  $n$  vertices and  $m$  edges shows that the expected number of conflicts from the first stage is low and for  $p \leq \frac{n}{\sqrt{2m}}$  the algorithm is expected to provide a nearly linear speedup. We also extend this idea and present a second parallel algorithm that improves on a given coloring.

The presented algorithms have been implemented using OpenMP on a Cray Origin 2000. Experimental results on a number of very large graphs show that the algorithms yield good speedup and produce colorings of comparable quality to that of their sequential counterparts. The fact that we are using OpenMP makes our implementation significantly simpler and easier to verify than if we had used a distributed memory programming environment such as MPI.

The rest of this paper is organized as follows. In Section 2 we give some background on the graph coloring problem and previous efforts made to solve it in parallel. In Section 3 we describe our new parallel graph coloring algorithms and analyze their performance on the PRAM model. In Section 4 we

present and discuss results from experiments performed on the Cray Origin 2000. Finally, in Section 5 we give concluding remarks.

## 2 Background

In this section we give a brief overview of previous work on developing fast sequential and parallel coloring algorithms. We also introduce some graph notations used in this paper.

For a graph  $G = (V, E)$ , we denote  $|V|$  by  $n$ ,  $|E|$  by  $m$ , and the degree of vertex  $v_i$  by  $deg(v_i)$ . Moreover, the maximum, minimum, and average degree in a graph  $G$  are denoted by  $\Delta$ ,  $\delta$ , and  $\bar{\delta}$  respectively.

As mentioned in Section 1 there exist several fast sequential coloring heuristics that are very effective in practice. These algorithms are all based on the same general greedy framework: A vertex is selected according to some predefined criterion and then colored with the smallest valid color. The selection and coloring continues until all the vertices in the graph are colored.

Some of the suggested coloring heuristics under this general framework include Largest-degree-First-Ordering (LFO) [17], Incidence-Degree-Ordering (IDO) [4], and Saturation-Degree-Ordering (SDO) [2]. These heuristics choose at each step a vertex  $v$  with the maximum “degree” of some form among the set of uncolored vertices. In LFO, the standard definition of degree of a vertex is used. In IDO, incidence degree is defined as the number of already colored adjacent vertices, whereas in SDO one only considers the number of differently colored adjacent vertices. First Fit (FF) is yet another, simple variant of the general greedy framework. In FF, the next vertex from some arbitrary ordering is chosen and colored. Intuitively, in terms of quality of coloring, these heuristics can roughly be ranked in an increasing order as FF, LFO, IDO, and SDO. Note that for a graph  $G$  the number of colors used by any sequential greedy algorithm is bounded from above by  $\Delta + 1$ . On the

### Algorithm 1

```
ParallelColoring( $G = (V, E)$ )  
begin  
   $U \leftarrow V$   
   $G' \leftarrow G$   
  while ( $G'$  is not empty) do in parallel  
    Find an independent set  $I$  in  $G'$   
    Color the vertices in  $I$   
     $U \leftarrow U \setminus I$   
     $G' \leftarrow$  graph induced by  $U$   
  end-while  
end
```

Figure 1: A parallel coloring heuristic

average, however, it has been shown that for *random* graphs FF is expected to use no more than  $2\chi(G)$  colors, where  $\chi(G)$  is the chromatic number of  $G$  [10]. In terms of run time, FF is clearly  $O(m)$ , LFO and IDO can be implemented to run in  $O(m)$  time, and SDO in  $O(n^2)$  time [2, 11].

When it comes to parallel graph coloring, a number of the existing fast heuristics are based on the observation that an independent set of vertices can be colored in parallel. Algorithm 1 outlines a general parallel heuristic based on this observation.

Depending on how the independent set is chosen and colored, Algorithm 1 specializes into a number of variants. The Parallel Maximal Independent set (PMIS) coloring is one variant. This is a heuristic based on Luby's maximal independent set finding algorithm [14]. Other variants are the asynchronous parallel heuristic by Jones and Plassmann (JP) [11], and the Largest-Degree-First(LDF) heuristic developed independently by Gjertsen Jr. et al. [9] and Allwright et al. [1].

All of these algorithms are developed for distributed memory parallel computers. Allwright et al. made an experimental, comparative study by implementing the PMIS, JP, and LDF coloring algorithms on both SIMD

and MIMD parallel architectures [1]. They report that they did not get speedup for any of these algorithms.

Jones and Plassmann [11] do not report on obtaining speedup for their algorithms either. They state that “the running time of the heuristic is only a slowly increasing function of the number of processors used”.

### 3 New Parallel Graph Coloring Heuristics

In this section we present two new parallel graph coloring heuristics and analyze their performance on the PRAM model. Our heuristics are based on block partitioning – dividing the vertex set (given in an arbitrary order) into  $p$  successive blocks of equal size. No effort is made to minimize the number of *crossing* edges i.e., edges whose end points belong to different blocks. Obviously, because of the existence of crossing edges, the coloring subproblems defined by each block are not independent.

#### 3.1 A New Parallel Algorithm

The strategy we employ consists of three phases. In the first phase, the input vertex set  $V$  of graph  $G = (V, E)$  is partitioned into  $p$  blocks as  $\{V_1, V_2, \dots, V_p\}$  such that  $|V_i| = n/p$ ,  $1 \leq i \leq p$ . The vertices in each block are then colored in parallel using  $p$  processors. The parallel coloring comprises of  $n/p$  parallel steps and proceeds with synchronization barriers at the end of each step. When coloring a vertex, *all* its previously colored neighbors, both the local ones and those found on other blocks, are taken into account. In doing so, two processors may simultaneously be attempting to color vertices that are adjacent to each other. If these vertices are given the same color, the resulting coloring becomes invalid and hence we call the coloring obtained a *pseudo coloring*. In the second phase, each processor  $p_i$  checks whether vertices in  $V_i$  are assigned valid colors by comparing the color of a vertex against all its neighbors that were colored at the same parallel

step in the previous phase. This checking step is also done in parallel. If a conflict is discovered, one of the endpoints of the edge in conflict is stored in a table. Finally, in the third phase, the vertices stored in this table are colored sequentially. Algorithm 2 provides the details of this strategy.

**Algorithm 2**

*BlockPartitionBasedColoring*( $G, p$ )

begin

1. Partition  $V$  into  $p$  equal blocks  $V_1 \dots V_p$ , where  $\lfloor \frac{n}{p} \rfloor \leq |V_i| \leq \lceil \frac{n}{p} \rceil$ 
    - for  $i = 1$  to  $p$  do in parallel
      - for each  $v_j \in V_i$  do
        - assign the smallest legal color to vertex  $v_j$
        - barrier synchronize
    - end-for
  2. for  $i = 1$  to  $p$  do in parallel
    - for each  $v_j \in V_i$  do
      - for each neighbor  $u$  of  $v_j$  that is colored at the same parallel step do
        - if  $color(v_j) = color(u)$  then
          - store  $\min\{u, v_j\}$  in table  $A$
        - end-if
      - end-for
    - end-for
  3. Color the vertices in  $A$  sequentially
- end

Figure 2: Block partition based coloring

**3.1.1 Analysis**

Our analysis is based on the PRAM model. With out loss of generality we assume that  $n/p$ , the number of vertices per processor, is an integer. Let the vertices on each processor be numbered from 1 to  $n/p$  and the parallel time used for coloring be divided into  $n/p$  time slots. We assume that the coloring

proceeds with synchronizing barriers at the end of each time unit  $t_j$ . This means, at each time unit  $t_j$ , processor  $p_i$  colors vertex  $v_j \in V_i$ ,  $1 \leq j \leq n/p$  and  $1 \leq i \leq p$ .

Our first result gives an upper bound on the *expected* number of conflicts (denoted by  $K$ ) created at the end of Phase 1 of Algorithm 2.

**Lemma 3.1** *The expected number of conflicts created at the end of Phase 1 of Algorithm 2 is at most about  $\frac{\bar{\delta}(p-1)}{2}$ .*

**Proof:** Consider a vertex  $x \in V$  that is colored at time unit  $t_j$ ,  $1 \leq j \leq n/p$ . Assuming that the neighbors of  $x$  are randomly distributed, the *expected* number of neighbors of  $x$  that are concurrently colored at time unit  $t_j$  is given by

$$\frac{p-1}{n-1} \text{deg}(x) \tag{1}$$

If we sum (1) over all vertices in  $G$  we count each pair of adjacent vertices that are colored simultaneously twice. Moreover each term in the sum represents only a potential conflict since two adjacent vertices could be colored simultaneously and yet be assigned different colors. The sum thus gives an upper bound on the expected number of conflicts. Therefore we have,

$$E[K] \leq (1/2) \sum_{x \in V} \frac{p-1}{n-1} \text{deg}(x) \tag{2}$$

$$= (1/2) \frac{p-1}{n-1} (2m) \tag{3}$$

$$= (1/2) \bar{\delta} (p-1) (n/n-1) \tag{4}$$

$$\approx \frac{\bar{\delta}(p-1)}{2} \tag{5}$$

In going from (3) to (4), the identity  $\bar{\delta} = \frac{\sum_{v \in V} \text{deg}(v)}{n} = \frac{2m}{n}$  is used. For large values of  $n$ ,  $(n/n-1) \approx 1$  and hence the transition from (4) to (5).

□

We now look at the expected<sup>1</sup> run time of Algorithm 2. To do so, we

---

<sup>1</sup>Expected time complexity expressions are identified by the prefix  $E$ .

introduce a graph attribute called *relative sparsity*  $r$ , defined as  $r = \frac{n^2}{m}$ . Note that  $1/r$ , the ratio of the actual number of edges to the total possible number of edges, shows the density of the graph. The following Lemma states that for bounded degree graphs and for  $p \leq \sqrt{\frac{r}{2}}$ , Algorithm 2 provides an almost linear speedup compared to the sequential First Fit algorithm.

**Lemma 3.2** *On a CREW PRAM, Algorithm 2 colors the input graph consistently in  $EO(\Delta n/p)$  time when  $p \leq \sqrt{\frac{r}{2}}$  and in  $EO(\Delta \bar{\delta} p)$  time when  $p > \sqrt{\frac{r}{2}}$ .*

**Proof:** Note first that since Phase 3 resolves all the conflicts that are discovered in Phase 2, the coloring at the end of Phase 3 is a valid one. Both Phase 1 and 2 require concurrent read capability and thus the required PRAM is CREW. The overall time required by Algorithm 2 is  $T = T_1 + T_2 + T_3$ , where  $T_i$  is the time required by Phase  $i$ . Both Phase 1 and 2 consist of  $n/p$  parallel steps. The number of operations in each parallel step is proportional to the degree of the vertex under investigation. The degree of each vertex is bounded from above by  $\Delta$ . Thus,  $T_1 = T_2 = O(\Delta n/p)$ . The time required by the sequential step (Phase 3) is  $T_3 = O(\Delta K)$  where  $K$  is the number of conflicts discovered in Phase 2. From Lemma 3.1,  $E[K] = O(\bar{\delta} p)$ . Substituting yields,

$$T = T_1 + T_2 + T_3 = EO(\Delta(n/p + \bar{\delta} p)) \quad (6)$$

The overall time  $T$  is thus determined by how  $n/p$  compares with  $\bar{\delta} p$ . Using the identity  $\bar{\delta} = \frac{2m}{n}$ , we see that for  $p \leq \sqrt{\frac{n^2}{2m}} = \sqrt{\frac{r}{2}}$ , the term  $n/p$  dominates giving an overall running time of  $EO(\Delta n/p)$ . For  $p > \sqrt{\frac{r}{2}}$ , the term  $\bar{\delta} p$  dominates and the overall time becomes  $EO(\Delta \bar{\delta} p)$ . □

The condition on the number of processors in Lemma 3.2 is satisfied by most graphs that arise from practical applications and currently available

parallel computers. To see this, consider a graph with a density of 0.01% ( $r = 10000$ ). Then  $\sqrt{\frac{r}{2}} = 70$  whereas one usually uses less than 70 processors in a parallel application.

## 3.2 Reducing the Number of Colors

In this section we show how Algorithm 2 can be modified to use fewer colors. This is motivated by the idea behind Culberson's Iterated Greedy (IG) coloring heuristic [5]. IG is based on the following result, stated here without proof.

**Lemma (Culberson) 3.3** *Let  $C$  be a  $k$ -coloring of a graph  $G$ , and  $\pi$  a permutation of the vertices such that if  $C(v_{\pi(i)}) = C(v_{\pi(l)}) = c$ , then  $C(v_{\pi(j)}) = c$  for  $i < j < l$ . Then, applying the First Fit algorithm to  $G$  where the vertices have been ordered by  $\pi$  will produce a coloring using  $k$  or fewer colors.*

From Lemma 3.3, we see that if FF is reapplied on a graph where the vertex set is ordered such that vertices belonging to the same color class<sup>2</sup> in the previous coloring are listed consecutively, the new coloring is better or at least as good as the previous coloring. There are many ways in which the vertices of a graph can be arranged satisfying the condition of Lemma 3.3. One such ordering is the reverse color class ordering [5]. In this ordering, the color classes are listed in reverse order of their introduction. This has a potential for reducing the number of colors used since one now proceeds by first coloring vertices that could not be colored with low values in the previous coloring.

Our improved coloring heuristic has 4 phases, one more phase than Algorithm 2. The first phase is the same as Phase 1 of Algorithm 2. Let the coloring number used by this phase be  $ColNum$ . During the second phase,

---

<sup>2</sup>Vertices of the same color constitute a color class

the pseudo coloring of the first phase is used to get a reverse color class ordering of the vertices. The second phase consists of  $ColNum$  steps. In each step  $i$ , the vertices of color class  $ColNum - i - 1$  are colored *afresh* in parallel. The remaining two phases are the same as Phases 2 and 3 of Algorithm 2. The method just described is outlined in Algorithm 3.

**Algorithm 3**

*ImprovedBlockPartitionBasedColoring*( $G, p$ )

begin

1. As Phase 1 of Algorithm 2

{At this point we have the pseudo independent sets  $ColorClass(1) \dots ColorClass(ColNum)$  }

2. for  $k = ColNum$  down to 1 do

Partition  $ColorClass(k)$  into  $p$  equal blocks  $V'_1 \dots V'_p$

for  $i = 1$  to  $p$  do in parallel

for each  $v_j \in V'_i$  do

assign the smallest legal color to vertex  $v_j$

end-for

end-for

end-for

3. As Phase 2 of Algorithm 2

4. As Phase 3 of Algorithm 2

end

Figure 3: Modified block partition based coloring

Each color class at the end of Phase 1 is a pseudo independent set. Hence block partitioning of the vertices of each color class results in only a few crossing edges. In other words, the number of conflicts expected at the end of Phase 2 ( $K_2$ ) should be smaller than the number of conflicts at the end of Phase 1 ( $K_1$ ). Thus, in addition to improving the quality of coloring, Phase 2 should also provide a reduction in the number of conflicts. Note that conflict checking and removing steps are included in Phases 3 and 4 to ensure that any remaining conflicts are resolved.

The following result shows that Phase 2 reduces the upper bound on the number of conflicts from Phase 1 by a factor of  $O(\Delta^2 p/m)$ .

**Lemma 3.4** *The upper bound on the expected number of conflicts at the end of Phase 2 of Algorithm 3 is reduced by a factor of  $O(\Delta^2 p/m)$  compared with the upper bound on the number of conflicts from Phase 1.*

**Proof:** Consider a color class  $w$  from the coloring obtained at the end of Phase 1 of Algorithm 3. Let the graph induced by the vertices of this color class be  $G' = (V', E')$  and  $n' = |V'|$ ,  $m' = |E'|$ . Consider a vertex  $x \in V'$  that is colored at time unit  $t_j$ ,  $1 \leq j \leq n'/p$ , and let  $deg'(x)$  be its degree in  $G'$ . Using Lemma 3.1, the expected number of conflicts at the end of Phase 1 is  $O(\bar{\delta}p)$ . Noting that there are  $m$  edges in the input graph  $G$  to Algorithm 3, the probability that an arbitrary edge in  $G$  consists of a conflict is  $O(\bar{\delta}p/m) = O(p/n)$ . Therefore we expect,  $deg'(x) \leq \frac{p}{n} deg(x)$ . Using the same argument as in Lemma 3.1, the expected number of neighbors of  $x$  that are concurrently colored at time unit  $t_j$  is  $\frac{p-1}{n'-1} deg'(x)$ . Thus the number of conflicts created due to the vertices of color class  $w$  (denoted by  $K'$ ) is bounded as follows.

$$E[K'] \leq \sum_{x \in V'} \frac{p(p-1)}{n(n'-1)} deg(x) \quad (7)$$

$$= \frac{p}{n}(p-1) \frac{\sum_{x \in V'} deg(x)}{n'-1} \quad (8)$$

$$= O(p^2 \Delta/n) \quad (9)$$

Recall that there are at most  $\Delta + 1$  colors at the end of Phase 1. Therefore,  $K_2$ , the total number of expected conflicts at the end of Phase 2, is

$$E[K_2] = O\left(\frac{p^2 \Delta^2}{n}\right) \quad (10)$$

Noting that  $E[K_1] = O(\frac{mp}{n})$ , we see that  $\frac{E[K_2]}{E[K_1]} = O(\frac{\Delta^2 p}{m})$  as claimed.

□

## 4 Experimental Results

In this section, we experimentally demonstrate the performance of the algorithms developed in Section 3. The experiments have been performed on a Cray Origin 2000, a CC-NUMA machine consisting of 128 MIPS R1000 processors. The new algorithms have been implemented in Fortran 90 and parallelized using OpenMP[16]. We have also implemented the sequential versions of FF and IDO to use as benchmarks.

The test graphs used in our experiments are divided into three categories as Problem Set I, II, and III (see Table 1). Problem Sets I and II consist of graphs (matrices) that arise from finite element methods<sup>3</sup>. Problem Set III consists of matrices that arise in eigenvalue computations [15].

### 4.1 Implementation

Here we illustrate how our parallel algorithms are implemented using OpenMP. The following few lines of code show a sketch of the implementation of Phase 1 of Algorithm 2. In the code, the input set of vertices is represented by the integer array `vertex`. The routine `assign_color(v)` assigns the smallest valid color to vertex number  $v$ . The routine `mp_barrier` is an OpenMP library routine that enables barrier synchronization. The number of vertices per processor is calculated and stored in the variable `blocksize`.

```
!$omp parallel do schedule(static, blocksize) private(i) shared(vertex)
  do i = 1, number_of_vertices
    call assign_color(vertex(i))
    call mp_barrier
  enddo
```

In addition to the standard OpenMP directives we have used data distribution directives provided by SGI to ensure that most cache misses are satisfied

---

<sup>3</sup>We thank George Karypis for making these matrices available on-line [12].

from local memory.

Algorithm 2 runs on a CREW PRAM model. On this model multiple read accesses to a memory location are allowed, whereas multiple write accesses are serialized. But what happens when a memory location is accessed for both read and write at the same time? This situation may arise in our algorithm but the CREW variant of PRAM does not account for it. In our implementation, in order to avoid reading garbage values, we disallow access to a memory location while it is being written by using the ATOMIC directive in OpenMP.

## 4.2 Synchronization Overhead

The barrier synchronization in Phase 1 of Algorithm 2 is introduced basically in order to identify the parallel step  $t_j$  ( $1 \leq j \leq n/p$ ) during which a vertex was colored. This information is used for two purposes: First, in Phase 1 to identify already colored neighbors of a vertex and secondly, in Phase 2 to identify the neighbors of a vertex that are colored at the same parallel step as itself. Although the barrier enables us to realize these purposes, its implementation incurs a large overhead. An alternative approach to overcome this is to use an asynchronous version of Algorithm 2. In each parallel step of both Phases 1 and 2 of the asynchronous version, *all* the neighbors of a vertex under investigation, irrespective of the parallel step during which they were colored, are considered. We have implemented and tested both the asynchronous and synchronous versions of Algorithm 2. The obtained results show that the asynchronous version runs faster by a factor of 3 to 5. Hence the results discussed in Section 4.3 are for the asynchronous versions of Algorithm 2 and Algorithm 3.

### 4.3 Discussion

**Table 1** provides some statistics about the test graphs. It also lists the number of colors required to color the graphs using sequential FF and IDO (shown under columns  $\chi_{FF}$  and  $\chi_{IDO}$  respectively).

**Table 2** lists results obtained using our first parallel coloring heuristic (Algorithm 2). The number of blocks (processors) is given in column  $p$ . Columns  $\chi_1$  and  $\chi_3$  give the number of colors used at the end of Phases 1 and 3 respectively. The number of conflicts that arise in Phase 1 are listed under the column labeled  $K$ . The column labeled  $\frac{\delta(p-1)}{2}$  gives the theoretically expected upper bound on the number of conflicts as predicted by Lemma 3.1. The time in milliseconds required by the different phases are listed under  $T_1$ ,  $T_2$ ,  $T_3$ , and the last column  $T_{tot}$  gives the total time used. The column labeled  $S_{par}$  lists the speedup obtained compared to the time used by running Algorithm 2 on 1 processor ( $S_{par}(p) = \frac{T_{tot}(1)}{T_{tot}(p)}$ ). The last column,  $S_{seqFF}$ , gives the speedup obtained by comparing against a straight forward sequential FF ( $S_{seqFF}(p) = \frac{T_1(1)}{T_{tot}(p)}$ ).

The results in column  $K$  of Table 2 show that in general, the number of conflicts that arise in Phase 1 is small and grows as a function of the number of blocks (or processors)  $p$ . This agrees well with the result from Lemma 3.1. We see that for the relatively dense graphs the actual number of conflicts is much less than the bound given by Lemma 3.1.

The run times obtained show that Algorithm 2 performs as predicted by Lemma 3.2. Particularly, the time required for recoloring incorrectly colored vertices is observed to be practically zero (in the order of a few micro seconds) for all our test graphs. This is not surprising as the obtained value of  $K$  is negligibly small compared to the number of vertices in a given graph.

As results in columns  $T_1$  and  $T_2$  indicate, the time used to detect conflicts is approximately the same as the time used to do the initial coloring. This makes the running time of the algorithm using one processor approximately

double that of the sequential FF. This in turn reduces the speedup obtained compared to the sequential FF by a factor of 2. The speedup obtained compared to running the parallel algorithm on one processor gets its best values for the two largest graphs `mrng3` and `dense2`.

**Table 3** lists results of Algorithm 3. The number of colors used at the end of Phases 1 and 2 are listed in columns  $\chi_1$  and  $\chi_2$ , respectively. The coloring at the end of Phase 2 is not guaranteed to be conflict-free. Phases 3 and 4 detect and resolve any remaining conflicts. Column  $\chi_4$  lists the number of colors used at the end of Phase 4. The number of conflicts at the end of Phases 1 and 2 are listed under  $K_1$  and  $K_2$ , respectively. The time elapsed (in milliseconds) in the various stages are given in columns  $T_1$ ,  $T_2$ ,  $T_3$ ,  $T_4$ , and  $T_{tot}$ . Speedup values in column  $S_{par}$  are calculated as in the corresponding column of Table 2. The column  $S_{2seqFF}$  gives speedups as compared to Culberson’s IG restricted only to two iterations ( $S_{2seqFF} = \frac{T_1(1)+T_2(1)}{T_{tot}(p)}$ ).

Results in column  $\chi_2$  confirm that Phase 2 of Algorithm 3 reduces the number of colors used by Phase 1. This is especially true for test graphs from Problem Sets II and III, which contain relatively denser graphs than Problem Set I. Comparing the results in column  $\chi_2$  with the results in the  $\chi_{IDO}$  column of Table 1, we see that in general the quality of the coloring obtained using Algorithm 3 is comparable with that of the IDO algorithm. IDO is known to be one of the most effective coloring heuristics [4].

From column  $K_2$  we see that the number of conflicts that remain after Phase 2 of Algorithm 3 is zero for almost all test graphs and values of  $p$ . The only occasion where we obtained a value other than zero for  $K_2$  was using  $p = 12$  for the graphs `dense1` and `dense2`. These results agree well with the claim in Lemma 3.4.

## 5 Conclusion

We have presented a new parallel coloring heuristic suitable for shared memory programming. The heuristic is fast and simple and yields reasonably good speedup for graphs of practical interest run on a realistic number of processors. We have also introduced a second heuristic that can improve on the quality of coloring obtained. Experimental results conducted on both heuristics using OpenMP validate the theoretical analysis performed using the PRAM model.

One of the main arguments against using OpenMP has been that it does not give as good speedup as a more dedicated message passing implementation using MPI. The results in this paper show an example where the opposite is true, the OpenMP algorithms have better speedup than existing message passing based algorithms. Moreover, implementing the presented algorithms in a message passing environment would have required a considerable effort and it is not clear if this would have led to efficient algorithms. Implementing these algorithms using OpenMP is a relatively straight forward task as all the communication is hidden from the programmer.

We believe that the method used in these coloring heuristics can be applied to develop parallel algorithms for other graph problems and we are currently investigating this in problems related to sparse matrix computations.
